**ABSTRACT**

**Purpose:** Progressive loss of dopaminergic neurons of the substantia nigra pars compacta (SNc) in Parkinson’s disease (PD) leads to impairment of motor skills. Several evidences show that the role of serotonergic system in regulation of normal movement is pivotal and mediates via 5-HT$_{1A}$ receptors. Our previous study has shown that fluoxetine in acute injections able to attenuate catalepsy in 6-hydroxydopamine (6-OHDA)-lesioned rats. Since drugs are used chronically in clinic, in this study we attempted to evaluate effect of chronic administration of fluoxetine on 6-OHDA-induced catalepsy. **Methods:** Catalepsy was induced by unilateral infusion of 6-OHDA (8 μg/2 μl/rat) into the central region of SNc and assayed by using bar-test. Fluoxetine (1, 2.5, 5 and 10 mg/kg) was injected intraperitoneally (ip) for 10 days and its anti-cataleptic effect was assessed at the 10th day. **Results:** Fluoxetine in high doses (5 and 10 mg/kg) worsened 6-OHDA-induced catalepsy while it had anti-cataleptic effect at the dose of 1mg/kg. The anti-cataleptic effect of fluoxetine (1mg/kg) was reversed by co-administration with NAN-190 (0.5 mg/kg, ip), as a5-HT$_{1A}$ receptor antagonist. **Conclusion:** According to the results it can be concluded that fluoxetine has anti-cataleptic effect in parkinsonian rats only at low doses, whereas at higher doses it worsens catalepsy. It’s anti-cataleptic effect is exerted through affecting on 5-HT$_{1A}$ receptors. However, at high doses other mechanisms may be involved. Further clinical studies are needed to prove it’s possible clinical application as an adjuvant therapy in reducing catalepsy of PD.

**Introduction**

Parkinson’s Disease (PD) is the second most common neurodegenerative disorder that is characterized by a marked loss of dopaminergic neurons of mainly the substantia nigra pars compacta (SNc) leading to a reduction of dopamine (DA) in the striatum. Dopamine deficiency results in motor disabilities, such as muscle rigidity, akinesia, tremor and postural abnormalities as well as cognitive disturbances.1-3 Investigation of PD in animals is based on modeling of the disease by injection of some neurotoxins such as 6-OHDA that selectively destroys catecholaminergic neurons. Intracerebral injection of 6-OHDA into the rat nigrostriatal pathway degenerate virtually all dopaminergic neurons in the SNc and leading to stable motor deficits.3,4 In 6-OHDA-treated rats hyperinnervation of serotonergic (5-HT) fibers within the affected area takes place which compensate some activities of lost dopaminergic neurons.5-7 All components of basal ganglia receive serotonergic neurons from dorsal raphe nucleus.8 It seems that serotonergic system has a pivotal role in regulation of voluntary movements and disturbances in serotonine transmission might contribute to the neural mechanisms underlying disorders of basal ganglia such as PD, Tourette's syndrome and obsessive compulsive disorder.9,10 Thus 5-HT transmission may be critical in treating the symptoms of PD and other motor disorders.8 Several studies have shown anti-cataleptic effect of 5HT$_{1A}$ agonists in rodent model of PD but the effect of selective serotonin reuptake inhibitors (SSRIs) in improving of catalepsy is controversial.9,11 Our previous study indicated that single-dose administration of flouxetine could abolish catalepsy in 6-OHDA lesioned rats.5 Since the long-term effect of drugs can vary with their acute administration, therefore in this study we attempted to investigate the chronic effect of flouxetine in catalepsy induced by 6-OHDA.

**Materials and Methods**

**Chemicals**
All chemicals were purchased from Sigma Chemical Co. (USA). Solutions were prepared freshly on the days of experimentation. Fluoxetine and 1-(2-...
methoxyphenyl)-4-[4-(2-pthalimidino)butyl]piperazine hydrobromide (NAN-190) were dissolved in 0.9% saline and 6-OHDA was dissolved in 0.9% saline containing 0.2% (w/v) ascorbic acid. The drugs were injected intraperitoneally (ip) except for 6-hydroxydopamine (6-OHDA) which was injected into right subestentia nigra pars compacta (SNc) in a total volume of 8 μl/rat with a constant injection rate of 0.2 μl/min.

**Animals**

The animals were carried out on male Wistar rats weighing between 270-300 g. Before and during of study these animals were kept in polypropylene cages, four per cage, under standard conditions (12:12h) light/dark cycle at an ambient temperature about 25±2°C and had access to standard pellet and water ad libium. Animals were acclimated to the testing conditions 2 days before the behavioral assessments were done. All of the procedures were carried out under the ethical guidelines of Tabriz University of Medical Sciences.

**Surgical procedures**

The animals were anesthetized intraperitoneally by ketamine (50 mg/kg) and xylazine (5 mg/kg). After deep anesthesia, rats were fixed in a stereotaxic frame in the flat skin positions. Scalp hairs of the rats were completely shaved with a standard electric shaving machine, swabbed with povidone iodine and a central incision made to reveal skull. A 0.7 millimeter bar hole was drilled and 23 gauge sterile stainless steel cannula, as a guide cannula inserted for subsequent injection of 6-OHDA in to the SNc. The coordinates for this site were based on the rat brain atlas: anteroposterior (AP): -5.0 mm from the bregma; mediolateral (ML): ±2.1 mm from the midline and dorsoventral (DV): -7.7 from the skull. Desipramine (25 mg/kg) was injected intraperitoneally 30 min before intra-nigral injection of 6-OHDA to avoid degeneration of noradrenergic neurons. Then 6-OHDA (8 μg/2μl/rat) was dissolved in 0.9% saline containing 0.2% (w/v) ascorbic acid. The infusion pump at the flow rate of 0.2 μl/min into the right subestentia nigra pars compacta. At the end of injection, guide cannula was kept for an additional 2 min and then slowly was withdrawed. All of these procedures were repeated in Sham-operated animals but they were received only 2 μl vehicle of 6-OHDA (0.9% saline containing 0.2% (w/v) ascorbic acid). For approving the accuracy of the site of injection, we provided a histological slice of striatum region that showed the site of inserted guide cannula in accordance with rat brain atlas. After three weeks as a recovery period, only the rats that showed marked immobilization in bare test were subjected to further experimentation. Then parkinsonian rats were divided randomly into equal groups and received once daily (9 a.m.) injections of fluoxetine (1, 2.5, 5 and 10 mg/kg, ip) for 10 days. NAN-190 (0.5 mg/kg, ip), as a 5-HT1A receptor antagonist, was injected concomitantly with the effective dose of fluoxetine.

**Catalepsy test**

Catalepsy was assessed by using of standard wooden bar test mean. Anterior limbs of rat gently extended on 9 cm high bar (0.9 cm in diameter). Elapsed time for each rat in this imposed posture was considered as a bar test time. The endpoint of catalepsy was designated to occur when both front paws were removed from the bar or if the animal moved its head in an exploratory manner. The cut-off time of the test was 720 seconds. This test was carried out 5, 60, 120 and 180 minutes after drugs administration in the 10th day. All observations were made between 9 AM and 4 PM.

**Statistical analysis**

Statistical analysis of each data set was calculated by use of SPSS software (version 16.0). Data were expressed as the mean±SEM, and were analyzed by one-way ANOVA in each experiment. In the case of significant variation (p<0.05), the values were compared by Tukey test.

**Results**

**Effect of Fluoxetine on 6-OHDA induced catalepsy**

Three groups of rats were shedoulded as normal (control), sham-operated (receiving 2 μl vehicle) and 6-OHDA (8 μg/2μl/rat, intra-SNc)-lesioned rats. As it has been shown in Figure 1, 6-OHDA could induce significant (p<0.001) catalepsy when compared with normal (control) and sham-operated animals. In other experiment five groups of 6-OHDA-lesioned rats received saline or one of four different doses of flouxetine (1, 2.5, 5 and 10 mg/kg, ip), respectively for 10 days. The results showed that flouxetine decreased the severity of 6-OHDA-induced catalepsy dose dependently (p < 0.001) (Figure 2).

Fluoxetine and 6-hydroxydopamine-induced catalepsy

Effect of NAN-190 co-treatment with fluoxetine on 6-OHDA-induced catalepsy

Three groups of 6-OHDA-lesioned animals received saline, fluoxetine (1 mg/kg, ip) or fluoxetine (1mg/kg ip) with NAN-190 (1mg/kg ip) respectively. The results showed that catalepsy-ameliorating effect of fluoxetine was reversed (p <0.001) by NAN-190 (Figure 3).

Discussion

Striatal DA deficiency or direct striatal damage for any reason may lead to PD which is characterized by tremor at rest, muscle rigidity and slowness of voluntary movement. 6-OHDA is a neurotoxin which is used generally to produce experimental model of PD. In this study intra-SNC injection of 6-OHDA caused noticeable catalepsy when assessed by bar test. This is standard test frequently used for evaluating catalepsy induced by 6-OHDA and neuroleptic drugs in rodents. Our results showed that chronic injections of fluoxetine for ten days attenuated 6-OHDA-induced catalepsy only at low doses. The most anti-cataleptic effect was observed at the dose of 1mg/kg, whereas fluoxetine at the high doses (5 and 10 mg/kg) trebled catalepsy. This may be due to increase of fluoxetine dose and involvement of some other neuronal effects. 5-HT1A receptors are widely distributed through the basal ganglia. They are located on dorsal raphe neurons with efferents to the striatum, and are also localized on cortical neurons sending glutamatergic projections to the basal ganglia. Release of dopamine following stimulation of 5-HT1A receptors in these regions is via the inhibition of adenyl cyclase and the opening of potassium channels. These findings show that modulation of 5-HT transmission by 5-HT1A receptor agonists can be a potential therapeutic approach in PD. On the other hand it is supposed that the striatum is a central neuroanatomical site for both antidyskinetic and anti-parkinsonian actions of 5-HT1A receptor agonists. In particular, the striatum and the output regions of the basal ganglia, the substantia nigra pars reticulata (SNr), and medial globus pallidus (GPM) receive a dense serotonergic input, thus suggesting a potential role for serotonin in PD. Specific serotonin reuptake inhibitors (SSRIs) which increase serotonin levels in synaptic cleft may have similar effect through affecting on 5-HT1A receptors. In this study, NAN-190 (5-HT1A receptor antagonist) reversed the catalepsy-improving effect of fluoxetine in 6-OHDA lesioned rats. Thus, it seems that low doses of fluoxetine improves anti-cataleptic effect of 6-OHDA by affecting on 5-HT1A receptors. While high dose of fluoxetine worsened catalepsy. It has been shown that serotonin modulates dopamine in basal ganglia by inhibiting its production and release. Furthermore, SSRIs may worsen the symptoms of pre-existing PD or depressive symptoms of anhedonia and social isolation. Worsening of PD by SSRIs can be explained by two mechanisms: First, over activation of serotonergic projections of dorsal raphe which project directly to the substantia nigra and subsequent inhibition of the dopaminergic neurons, second, extrapyramidal side effects of SSRIs. According to the results, we conclude that fluoxetine improves catalepsy of parkinsonian rats in a dose-dependent manner. This effect is mediated by the stimulation of 5-HT1A receptors. We suggest a possible clinical application for fluoxetine in attenuating catalepsy of PD. To prove this hypothesis further clinical investigations should be carried out.
