Abstract

Purpose: Bioadhesive polymers play an important role in biomedical and drug delivery applications. The aim of this study is to develop a sustained-release tablet for local application of Cetylpyridinium Chloride (CPC). This delivery system would supply the drug at an effective level for a long period of time, and thereby overcome the problem of the short retention time of CPC and could be used for buccal delivery as a topical anti-infective agent.

Methods: CPC bioadhesive tablets were directly prepared using 7 mm flat-faced punches on a hydraulic press. The materials for each tablet were weighted, introduced into the die and compacted at constant compression pressure. The dissolution tests were performed to the rotation paddle method and the bioadhesive strength of the tablets were measured.

Results: The results showed that as the concentration of polymer increased, the drug release rate was decreased. Also the type and ratio of polymers altered the release kinetic of Cetylpyridinium Chloride from investigated tablets. The bioadhesion strength increased with increasing the concentration of polymer and maximum bioadhesion strength was observed with HPMC K100M.

Conclusion: The selected formulation of CPC bioadhesive tablet can be used as a suitable preparation for continuous release of CPC with appropriate bioadhesion strength.

Introduction

Bioadhesive polymers play an important role in biomedical and drug delivery applications. Good adhesion and intimate contact between polymer carrier and tissue are desirable for use in these applications. Mucoadhesive systems are advantageous over conventional drug delivery systems due to their ability to increase the contact time of drug with the biological substrate, thus increasing drug absorption. Various bioadhesive mucosal dosage forms have been developed, which included adhesive tablets, gels, ointments, patches, and more recently films.1 Mucoadhesion is provided by the formation of non-covalent bonds such as hydrogen bonds and ionic interactions or physical entanglements between the mucus gel layer and polymers. Mediated by mucoadhesive polymers, the residence time of dosage forms on the GI-mucosa should be prolonged, which allows a sustained drug release at a given target site to maximize the therapeutic effect.2

A major difficulty for the successful eradication of infections of oral cavity is the dilution and rapid elimination of topically applied drugs due to the flushing action of saliva. The delivery system in which the drug is incorporated is therefore an important consideration and should be formulated to prolong retention of the drug in the oral cavity. Efficient local delivery of actives such as dental bleaches and antimicrobials to the oral cavity is compromised by a number of factors that dramatically reduce residence time, most notably the shear forces associated with speaking, swallowing and mastication, as well as dilution and washout caused by continuous saliva production.3

Typical polymers that have been used as mucoadhesive drug carriers are poly (acrylic acid), poly (methacrylate acid), cellulose derivatives, poly (ethylene oxide), lectin and chitosan.4 The PAA and its cross-linked commercial forms, Carbopol and polycarbophil exhibit strong mucoadhesive properties.5 Many attempts have been undertaken to improve the mucoadhesive properties of polymers by preparing copolymers, polymer conjugates or interpolymer complexes.5,6,7

CPC, an amphiphilic quaternary compound, has been used extensively in oral hygiene formulations.5 Valuable properties of CPC include solubility in water and alcohol, as well as its ability to reduce surface tension. A number of laboratory studies are available in the literature that report the broad spectrum activity of CPC on a range of organisms, including bacteria and yeast found in dental plaque.8,9 Bonesvoll and Gjerme have shown that a moderate plaque inhibition was obtained...
when CPC was applied twice daily as a mouthwash. Only when the frequency was increased to 4 times daily did the plaque inhibitory effect approach that of chlorhexidine. The differences in clinical effect could be explained from the retention time of the drug: the quaternary ammonium compounds were cleared from the mouth more rapidly than was chlorhexidine. Friman et al. prepared the cast film composed of ethylcellulose and CPC. The films exhibited sustained inhibition of Streptococcus mutans growth in vitro. The results of the clinical study proved that a single application of cetylpyridinium films decreased plaque accumulation for a period of 3 days. No changes in the total salivary flora were observed during the study.

The aim of this study is to develop a sustained-release tablet for local application of CPC. This delivery system would supply the drug at an effective level for a long period of time, and thereby overcome the problem of the short retention time of CPC and could be used for buccal delivery as a topical anti-infective agent.

### Materials and Methods

#### Materials

Cetyl pyridinium Chloride, magnesium stearate, potassium hydrogen phosphate and lactose were purchased from Merck Co. (Germany). Carbopol 934P and polycarbophill from BF Goodrich Co. (USA), and HPMC K100M were prepared from Colorcon Co. (UK). All chemicals and solvents were of analytical grade. Freshly double distilled water was used in the experiments.

#### Preparation of bioadhesive tablets

Six formulations (F1-F6) were directly prepared using 7 mm flat-faced punches on a hydraulic press. The materials for each tablet (Table 1) were weighed, mixed and introduced into the die and compacted at constant compression pressure using 1% (w/w) magnesium stearate.

#### In vitro dissolution

The dissolution tests were performed to the rotation paddle method (USP Pharmacopoeia 24). A dissolution apparatus (Caleva 8ST, Germany) was employed with a stirring rate of 100 rpm. The dissolution medium was 900 ml phosphate buffer (pH: 6.8). Samples of the solution were withdrawn at definite time intervals. The dissolution media was then replaced by fresh dissolution fluid to maintain a constant volume. The solution was passed through a filter and then the concentration of CPC in solution was measured with an ultraviolet spectrophotometer (Varian, Australia) at a wavelength of 258 nm after suitable dilution with the dissolution medium when necessary. The experiment was carried out in triplicate.

#### Kinetic analysis

In order to describe the kinetics of drug release from mucoadhesive tablets, various mathematical equation models (zero-order, first-order, Higuchi) were tested

\[
Q_t = k_0 t \\
\ln Q_t = \ln Q_0 - k_1 t \\
Q_t = k_2 t^{1/2}
\]

Where \(Q_t\) is the amount of drug released in time \(t\), \(Q_0\) is the initial amount of drug in the tablet and \(k_0\), \(k_1\) and \(k_{1/2}\) are the respective release rate constants for zero-order, first-order and Higuchi models. In order to define a model, that will represent a better fit for the formulations, dissolution data can be further analyzed by the Ritger and peppas and Korsmeyer equation

\[
M_t/M_\infty = k_0 t^n
\]

Where \(M_t\) corresponds to the amount of drug released in time \(t\), \(M_\infty\) is the total amount of drug that must be released at infinite time, \(k_0\) is a constant and ‘\(n\)’ is the release exponent indicating the type of drug release mechanism.

#### Determination of bioadhesive strength

To evaluate the bioadhesion strength, a tensile tester apparatus was designed similar to a tensile tester apparatus (Instron model 4301) and the bioadhesive strength of the tablets was measured according to previously published method by a tensile tester apparatus. After isolation of hairless abdominal skin of the rat, the dorsal section of abdominal skin of rat (mucosa part) was fixed on the head of diffusion cell and filled with phosphate buffer with pH 6.8. The same conditions were exactly used according to previously published method.

#### Statistical analysis

Statistical analysis was carried out by using the analysis of variance (ANOVA) with computer software SPSS 10. Tukey-Kramer multiple comparison tests were used to compare the group data.
Results and Discussion

Bioadhesive preparations are preferred for treatment of diseases of oral cavity because they can adhere to the mucosa, protect the diseased part, and retain the drug for the desired period. Examples of oral cavity diseases for which buccal dosage forms have been designed include: aphthous stomatitis, oral candidiasis, and periodontal disease. In the buccal region, a tablet may be adhered either to the buccal tissue (check) or the gingival. For local drug delivery, the highly keratinized epidermis of the gingival will present a barrier to systemic absorption. The buccal tablet must be sufficiently thin (1-2 mm) and of small diameter (6-8 mm), so as to be comfortable and not obtrusive when placed into the oral cavity. Bioadhesion is the phenomenon between two materials, which are held together for extended periods of time by interfacial forces. It is generally referred as bioadhesion when interaction occurs between polymer and epithelial surface, mucoadhesion when occurs with the mucus layer covering a tissue.

The adhesion force of mucoadhesive tablets is shown in Figure 1. The bioadhesion strength of mucoadhesive tablets were evaluated by method that described by Akbari et al. The results of this study clearly demonstrate that the changing the type of polymer can also change the bioadhesive strength of tablets. Maximum bioadhesive strength was seen with F3 (HPMC K100M). Also the results showed that the bioadhesion strength decreased with incorporation of lactose in formulations.

![Figure 1. Comparison of the mucoadhesive force of investigated cetylpyridinium buccal tablets containing carbopol 974P, polycarbophil, and HPMC K100M (n=3).](image)

Bioadhesive force means the force with which tablets bind to buccal mucous membranes. The bioadhesive forces of the tablet are affected by the shape of the tablet, the swelling degree of the tablet and the nature of the tablet components.17 Various classes of polymers have been investigated in order to meet the requirements for a mucoadhesive polymer, such as proper hydrogen-bonding functional groups, suitable wetting properties, swelling/water load properties, and sufficient flexibility for entanglement with the tissue mucus network. The mucosal surface is covered with a mucus layer, in which mucins are the major component. Mucins are highly glycosylated glycoproteins with a large peptide backbone and oligosaccharides as side chains. As a result, mucins are negatively charged at physiological pH. Mechanisms of polymer attachment to mucosal surfaces are not yet fully understood. However, certain theories of bioadhesion have suggested that it might occur via physical entanglement (diffusion theory) and/or chemical interactions, such as electrostatic, hydrophobic, hydrogen bonding, and Van der Waals interactions (adsorption and electronic theories).18 Formulation F2 was having lowest bioadhesive force because the carbopol 974P has a lower viscosity than the other two polymers. While formulation F5 containing HPMC K100M shows higher bioadhesion force due to higher viscosity. HPMC is a long chained, nonionic polymer and so its mucoadhesion is attributable to the formation of physical bonds or hydrogen bonding with the mucus components. HPMC possesses a large number of hydroxyl groups that are responsible for adhesion. Formation of hydrogen bonds between the hydrophilic functional groups of the mucoadhesive polymers and the mucus layer or the mucosal surface is a prerequisite for extensive and longer mucoadhesion. The increased sites for bond formation can explain the increase in bioadhesion with an increase in concentration. The higher mucoadhesive potential observed with formulations containing only HPMC is probably due to the controlled rate of hydration of HPMC as a nonionic polymer. This could in turn prevent the tablet from quick over hydration and formation of slippery and weak mucilage, which could be easily removed from the mucosal surface.19

From the above results it was found that polymers having high molecular weight and high viscosity exhibited higher adhesion. Chandira et al. prepared the mucoadhesive tablets of Clarithromycin by using the Carbopol 974P, HPMC K15M and HPMC K4M. They found that polymers having high molecular weight and high viscosity exhibited higher adhesion. HPMC K15M and Carbopol 974P were found to be having good mucoadhesive strength. HPMC and carbopol possesses hydroxy and carboxy groups respectively required for bioadhesion.20 Akbari et al evaluated the effect of fillers on the bucoadhesive propranolol hydrochloride tablets. The results that they obtained showed bioadhesion force increased with increasing the concentration of polycarbophil. It is clear that the formation of very thin and strong gel layer at the boundary might be necessary for adhesion. The viscosity of this layer is increased by adding polycarbophil and therefore the bioadhesion strength increases.21 Also Maniyar et al. stated that the strength of mucoadhesion can be influence by polymer concentration. Physical state of the delivery system defines the polymer concentration, with observational differences between semisolid and solid state platforms. In semisolid state, an optimum concentration exists for...
each polymer beyond which reduced adhesion occurs because a lower number of polymer chains are available for interpenetration with mucus. On other hand, solid dosage forms such as buccal tablets exhibit increased adhesive strength as the mucoadhesive polymer concentration increases.\textsuperscript{22}

**In vitro dissolution studies**

The effect of polymer type and addition of lactose on release rate are shown in Figure 2. The initial percentage drug release after 2 hour for F1, F2, F3, F4, F5 and F6 were 14.20, 48.48, 14.63, 48.02, 16.12 and 25.52 respectively. The percentage drug release after 8 hour for F1, F2, F3, F4, F5 and F6 were 39.91, 70.66, 35.63, 67.41, 26.87 and 50.59 respectively. The lowest release rate was observed with formulation F5 containing HPMC K100M and the highest release rate was observed with formulation F2 containing Carbopol and Lactose ($P<0.01$). The significant difference was not observed between F1-F3 and F2-F4 but there were the significant differences between the release rate of formulations F1 - F3 with F5 ($p<0.01$) and F2-F4 with F6 ($p<0.001$).

It was observed that the type of polymer influences the drug release pattern. Amount of polymer affects the drug release. Drug release from HPMC K100M was lesser owing to its high viscosity and also due to less permeability of water to HPMC K100M. As expected, the drug release rate was dependent on the viscosity grade and the concentration of the polymer used. Figure 2 shows the effect of replacement of HPMC, Polycarbophil and Carbopol 974P by lactose on the release profile of drug. The figure shows that replacement of polymer by lactose increases the release rate of drug from buccoadhesive tablets. Changing the polymer/filler ratio increases the release rate by altering the diffusivity of drug in gel layer. Water diffusivity depends only on the total concentration of viscosity inducing agents in the system irrespective of their nature or polymerization degree. Replacement of polymer by lactose decreases the concentration of polymer in gel layer and therefore diffusion of water into the tablet is facilitated. Lactose also decreases the tortuosity of the path of diffusion. The results confirmed the finding of Lapidus and Lordi that replacement polymer by either a soluble or an insoluble diluents increased dissolution rate.\textsuperscript{21} Also Diasa et al. formulated the mucoadhesive Acyclovir tablet with using the HPMC K100M. Their results showed high HPMC K100M content results in a greater amount of gel being formed. This gel layer increases the diffusion path length of the drug, hence controlling drug release via diffusion through the gel and erosion of the gel barrier. Its viscous nature also affects the diffusion coefficient of the drug. As a result, drug release was found to be decreased as the amount of HPMC K100M was increased.\textsuperscript{23}

**Kinetic evaluation**

Dissolution rate data were analyzed based on Eqs. (1-4) and their results are listed in Table 2. The results showed that altering the type of polymer and the ratio of two polymer, had effect on the release kinetic of CPC from buccoadhesive tablets and the highest correlation coefficient were achieved with the various models.

$k_0$: zero order release rate constant, $k_i$: first order release rate constant, $k_{H}$: Higuchi model release rate constant, $k_p$: Peppas model release rate constant, $n$: release exponent in Peppas model, $r^2$: definition coefficient, $SS$: sum of squares of errors

There are the following possible mechanisms by which drug release from a polymeric matrix may occur: (a) the first and the most often encountered mechanism is drug diffusion through the outside layers of the matrix, also known as “Fickian” release or “Case I” mechanism (b) non-Fickian or anomalous (c) “zero-order” release or “Case II” mechanism Another mechanism of release involves devices made from water-soluble or swellable polymers, where matrix swelling and drug diffusion occur concurrently. This mechanism has been described as non-Fickian or anomalous transport and the release is controlled by swelling and diffusion. However, in
Buccoadhesive tablet of cetylpyridinium chloride

practice, polymeric matrices release the drug via a combination of mechanisms. The exponent, \( n \), depends on the polymer swelling characteristics and the relaxation rate at the swelling front.\(^{24}\) The CPC release from matrix tablets containing different types of polymers showed a good fit into the Peppas equation, indicating combined effect of diffusion and erosion mechanisms for drug release. As shown in Table 2, release data fit well with this model as a correlation coefficient \((r^2)\) greater than 0.951 was obtained in all cases.

According to the criteria for release kinetics from swellable systems, a value of release exponent, \( n = 0.45, 0.45<\ n< 0.89, \) and \( 0.89<\ n<1.0 \) indicates Fickian (Case I) diffusion, non-Fickian (anomalous) diffusion and zero-order (Case II) transport, respectively.\(^{25}\) The value of diffusional coefficient, \( n \), for mucoadhesive matrices was 0.574-0.764 which indicates non-Fickian (anomalous) behaviour and that the drug partially diffuses through the swollen polymer matrix and also partly through the gradually expanding hydrated matrix with increasing diffusional path length.

**Conclusion**

In this study, the effect of type and amount of polymer on the bioadhesive strength and release rate of Cetylpyridinium Chloride were evaluated. Different mucoadhesive tablets were formulated to adhere to the buccal mucosa for a local CPC release. The dissolution rate, release kinetic and bioadhesion force of tablets were evaluated. The results showed that as the concentration of polymer increased, the release rate decreased. The lowest release rate observed with HPMC K100M. The bioadhesion strength of mucoadhesive tablets were evaluated by method that described by Akbari et al. the results showed that the highest bioadhesion force also was observed with HPMC K100M.
